19. KEY WORDS (Continue on reverse side if necessary and identify by block number) Coumarin laser dyes, solvent effects on emission, solvatochromic equations, Stokes shifts, dye fluorescence quantum yields and lifetimes 80 3 10 014 (Arthur M. Halpern)		
20. ABSTRACT (Continue on reverse side if necessary and identify by block number) The red shifts of absorption and emission bands of coumarin laser dyes were studied as a function of solvent polarity and hydrogen bonding. Spectra were correlated with solvent parameters, $\pi^*$ and $\alpha$ , and those sol- vents resulting in the largest Stokes shifts of dye emission were identified. Solvent effects on emission yield and lifetime revealed a major non-radia- tive decay path for dyes in which the 7-aminefunction is free to adopt a non-planar conformation. P. ALPHA

The red shifts of absorption bands of coumarin dyes in polar solvents correlate with the solvent polarity- polarizability parameter  $\pi^*$ . Emission frequencies correlate well with the hydrogen bonding parameter,  $\alpha$  and show a regular dependence on  $\pi^*$  if a solvent polarizability correction term is incorporated for chlorinated hydrocarbon and aromatic solvents. Quantum yield and lifetime measurements reveal that the reduced emission observed for dyes with non-rigid structures is associated with enhanced nonradiative decay in polar solvents. The solvent effect on fluorescence yield is interpreted in terms of the intervention of planar and non-planar excited species which appears to be general for polar dyes.

The strong emission of aminocoumarin dyes derives from the polar character of low-lying excited states.<sup>1</sup> The Stokes shift and yield of fluorescence and the potential for lasing are influenced by the maintenance of a large excited state dipole moment. Dye substitution patterns and dye medium both play important roles in dipole stabilization. Recent studies<sup>2</sup> suggest that relatively subtle medium (solvent) effects may be exploited in optimizing the output of dye lasers which employ coumarin dyes. We have examined the influence of solvent on the photophysical properties of a number of coumarin dyes and find certain regular and predictable functions of solvent polarity which are reported herein. Particular attention has been paid to the fall off in fluorescence yield in polar solvents which has been observed for dyes with non-rigid structures.<sup>1,3</sup> We are able to assign this effect to a non-radiative decay path on the basis of emission yield and lifetime measurements and using a current model of polar excited state dynamics.

Dyes chosen for study are the fluorinated aminocoumarins shown below with number designations, C1F (35), C6F (153), and C8F as previously reported<sup>1,5</sup> (numbers in parenthesis refer to the Eastman Kodak system<sup>3</sup>). Absorption data for a variety of solvents are shown in Table 1. Measured extinction coefficients were in the range,  $\epsilon = 15,000 - 20,000$ . The regular dependence of emission maxima on solvent polarity for non-hydrogen-bonding solvents was treated quantitatively using the solvent parameters  $\pi^*$ . This scale of solvent polarity has been developed by Kamlet and Taft<sup>6</sup> from absorption data for a number of aniline derivative indicator dyes and reflects solvent polarity-polarizability in the absence of specific interactions such as hydrogen bonding.

Correlations of absorption frequencies with  $\pi^*$  are shown in Figure 1. Linear least squares analysis of the data leads to the following equations describing the solvatochromic effect. (Correlation coefficients,  $r$ , are included).

$$\text{For ClF, } \nu_a = 26.5 - 1.67 \pi^* \quad (r = 0.942) \quad (1)$$

$$\text{For C6F, } \nu_a = 25.4 - 1.89 \pi^* \quad (r = 0.972) \quad (2)$$

$$\text{For C8F, } \nu_a = 26.1 - 1.78 \pi^* \quad (r = 0.977) \quad (3)$$

The intercepts of  $\nu_a$  vs.  $\pi^*$  plots approximate the absorption frequency for the reference solvent cyclohexane ( $\pi^* = 0$ ) and reflect the role of substituents in excited state dipole stabilization in the absence of any significant solvent dipole interaction. The greater excited state dipole stabilization for C6F over ClF is consistent with the introduction of electron donating alkyl groups at ring positions 6 and 8 for this series. The slopes of  $\pi^*$  plots reflect the strength of interaction of excited dye with solvent dipoles or induced dipoles, a susceptibility which is similar for the series.

Emission maxima and Stokes shift for the selected dyes (Table 2) were obtained from corrected fluorescence spectra recorded on a Perkin-Elmer MPF 44A spectrophotometer. Fluorescence quantum yields were obtained using quinine sulfate in 1.0 N  $\text{H}_2\text{SO}_4$  ( $\phi = 0.55$ ) as the fluorescence standard with refractive index and differential absorption corrections. Emission lifetimes were determined using single photon counting apparatus and analytical deconvolution methods previously described.<sup>7,8</sup> The emission quantum yield and lifetime results are collected in Table 3.

The well-known shift of emission maximum to longer wavelength and a general broadening of the fluorescence band on increase in solvent polarity<sup>1</sup> was reproduced in our study. The dependence on solvent polarity-polarizability was less regular, however, than that found for absorption measurements. Plots of  $\nu_f$  and  $\pi^*$  for ClF and C8F, for example, revealed a trend but were not strictly linear as illustrated in Figures 2 and 3.

In contrast to the emission data for aprotic (non-hydrogen bonding) polar solvents, fluorescence maxima for C6F and C8F in alcohols were readily correlated with a single solvent property. As shown in Figure 4, a linear relation was obtained with the Kamlet/Taft<sup>9</sup> parameter,  $\alpha$ , an empirically derived constant reflecting the ability of solvent to donate a hydrogen bond (implicating a specific dipole-dipole association with solute). Least squares analysis of the data provided the following expression relating fluorescence maxima and the hydrogen bonding parameter. (A less satisfactory correlation of  $\nu_f$ , vs.  $\alpha$  was obtained for the non-rigid dye.)

$$\text{For C6F, } \nu_f = 21.09 - 2.61 \alpha \quad (r = 0.978) \quad (5)$$

$$\text{For C8F, } \nu_f = 21.40 - 2.29 \alpha \quad (r = 0.990) \quad (6)$$

Solvatochromic equations reflecting red shifts of emission due to interaction with hydrogen bonding and non-hydrogen bonding solvents were obtained when the polarizabilities of different classes of aprotic solvents were taken into account. We noted that in the plots shown in Figures 2 and 3, the solvents responsible for most of the scatter were either aromatic (benzene, toluene) or chlorinated (tetrachloroethane). These classes of solvents with polarizabilities which exceed those of non-chlorinated aliphatic solvents have been shown to give deviant behavior in  $\pi^*$  correlations.<sup>10</sup> Thus, the following "all solvent" equation has been proposed<sup>10,11</sup> for regression analysis employing  $\alpha$ ,  $\pi^*$ , and a correction term for  $\pi^*$ ,  $d\delta$ , a measure of enhanced polarizability ( $\delta = 0.5$  for chlorinated solvents and 1.0 for aromatic solvents).

$$\nu_f = \nu_0 + b(\pi^* + d\delta) + a\alpha \quad (7)$$

Least squares multiple regression analysis<sup>11</sup> of the fluorescence data for the fluorinated coumarins led to the following solvatochromic equations.

$$\text{For ClF, } \nu_f = 22.8 - 3.50 (\pi^* - 0.20 \delta) + 1.42 \alpha \quad (r = 0.981) \quad (8)$$

$$\text{For C6F, } \nu_f = 21.9 - 3.28 (\pi^* - 0.20 \delta) + 1.52 \alpha \quad (r = 0.990) \quad (9)$$

$$\text{For C8F, } \nu_f = 22.3 - 3.32 (\pi^* - 0.20 \delta) + 1.20 \alpha \quad (r = 0.975) \quad (10)$$

The best fit of parameters for the emission data was provided by setting the scaling factor for the polarizability correction term,  $d = -0.20$ . This value is similar to that found ( $-0.19$ ) in an "all solvents" correlation of emission frequencies for a merocyanine dye similar to the coumarins, N,N-dimethyl-4(dichloro-1,3,5-triazinyl)aniline.<sup>11</sup>

Equations 8 - 10 allow the dissection of solvent shifts of emission frequencies into relative influences of solvent polarity and hydrogen bonding.<sup>†</sup> The solvatochromic equations also provide a means for predicting emission maxima and Stokes shifts for a wide variety of solvents whose  $\pi^*$  and  $\alpha$  parameters are known.<sup>9-10</sup> Notably, the largest Stokes shifts are predicted for non-chlorinated aliphatic solvents having high  $\pi^*$  values. Alcohols as a class provide large Stokes shifts as well, and among the alcohols differences in  $\nu_a - \nu_f$  are relatively small.

Changes in emission yield and lifetime accompanied the shift of dye emission to longer wavelengths with increase in solvent polarity. Some reduction in fluorescence yield was noted for all three selected dyes (Table 3), but the effect was most striking for ClF. This phenomenon, already associated with dye substitution pattern in which the amine geometry at the 7-position is nonrigid,<sup>3</sup> could in principle be the result of changes in either radiative or nonradiative decay parameters. These rate constants are readily calculated from fluorescence yield and lifetime data using the relationships:  $k_f = \phi_f / \tau_f$  and  $k_{nd} = 1 - \phi_f / \tau_f$ . The results in Table 4 show that the sharp fall off in relative fluorescence intensity for ClF is in part due to a diminished rate of radiative decay (as with the other

dyes) but the more important effect is a large increase in non-radiative deactivation. In fact a >200-fold range in  $k_{nd}$  for ClF contrasts with a <10-fold change for C6F and C8F.

The notion that a radiationless decay involving motion of the amine substituent for ClF is supported by other medium effect data. In the very polar ( $\epsilon = 42.5$ ) yet highly viscous ( $\mu = 945$  cP) solvent glycerol, C6F and C8F emission yields and lifetimes were further reduced (i.e., the trend for the very polar solvents continues) yet the effect on ClF was to restore emission parameters to values which are similar to those found for the rigid dyes.

We interpret the principle effect of solvent medium on fluorescence yield and lifetime for the coumarins in terms of a rotation dependent radiationless decay, an internal conversion of the emissive state to a twisted conformation which is relatively non-emissive. Thus, excitation leads to a polar, planar excited state of the dye which is moderately stabilized by interaction with solvent and which gives rise to most if not all observed fluorescence. This intramolecular charge-transfer or ICT state is nominally represented by a polar resonance structure, (see below), a form which is more important in the excited state than in the ground state. In very polar media and where structure permits the ICT state relaxes further to a fully charged (zwitterionic) excited species having a non-planar geometry (a TICT or twisted intramolecular charge transfer state). The model is adopted from the current proposal of Grabowski, Cowley, and Baumann<sup>13</sup> concerning the behavior of a variety of polar excited species.

Photophysical parameters for other dyes (e.g., Cl having a "free"  $-N(C_2H_5)_2$  group and ClO2, similar in structure to C6F)

have been measured in our laboratories with results consistent with the ICT - TICT model. However, within the family of coumarins there may be two exceptional groups of compounds. Dyes with an unsubstituted  $\text{-NH}_2$  substituent group such as C120<sup>14</sup> and C151<sup>15</sup> as well as coumarins substituted with the benzothiazole group (C7 and C30)<sup>14</sup> do not show significantly reduced emission yields and lifetimes in the most polar solvents. Differences in  $\text{NH}_2$  - vs.  $\text{NR}_2$  substituted dyes are consistent with recent calculations<sup>16</sup> on excited state rotational relaxation in substituted benzonitrile and related systems.

In summary, solvent effects on the position, intensity, and lifetime of emission of a group of representative coumarin dyes have been measured. Reduced emission yields in polar solvents, reminiscent of the behavior of rhodamine dyes,<sup>1</sup> and related effects of dye structure (rigid vs planar chromophore geometry) and dye solvent properties (polarity and viscosity) have been observed. Regular dependences of absorption and emission maxima on solvent polarity-polarizability and hydrogen bonding properties have been identified, providing some means for "solvent tuning" of emission bands.

We wish to thank Drs. A.N. Fletcher, P.R. Hammond, M.J. Kamlet, and F. De Schryver for helpful discussions, Drs. De Schryver, and Hammond for supplying data prior to publication, Dr. Kamlet for performing multiple regression analyses, and Dr. R.L. Atkins for providing coumarin dye samples. We thank the U.S. Office of Naval Research (Boston University) and the National Science Foundation (Northeastern University) for support and the NSF for an instrument grant.

#### FOOTNOTE

\*Solvent effects other than solvent polarity and hydrogen bonding have been considered. Coumarin emission frequencies for alcohol solvents have been correlated with the Hildebrand  $\delta$  parameter reflecting solvent cohesion.<sup>12</sup>
